DDOS (distributed denial of service) prevents any host from sending a packet of any kind for a specified time, usually between 30 and 60 seconds. Most often used for spamming people, I've always wondered if there are other uses. A webpage can be a DDOS. It is obviously a DOS to force people to visit the site and the server has to process and serve the request. Let's say I have a site with a PHP script that uses a MySQL database to display webpages to visitors. A user generates and uploads a single webpage. He generates his own \$_GET variable, passes it to the PHP script, and that script sends off an HTTP request to the server. The server processes it, checks the table in the MySQL database, and produces the response. The user receives this response, and his single HTTP request has been counted for the DDOS. End of DDOS. The script could also just send the request to one or more other PHP scripts, each of which would produce a response and count against the DDOS. So, what if he just generates and sends a variable indicating that he sent the request? This would satisfy part (1) of the DDOS script definition. However, would this violate the part (2), which says the request should be processed by the server? Or is the part (1) definition of DDOS (no matter how broadly it is used) really only applicable if the server processes the request? Seems to
